Summary of guidelines

These guidelines have been drawn up to help physicians manage adults with HIV/TB coinfection. We recommend that coinfected patients are managed by a multidisciplinary team that includes physicians who have expertise in the treatment of both tuberculosis and HIV.

We recommend that the optimal regimen be used in the treatment of tuberculosis. In the majority of cases, this will necessitate use of rifampicin and isoniazid. In the treatment of HIV, there is more flexibility of choice for many patients starting highly active antiretroviral therapy (HAART).

We recommend that if HIV treatment is started in patients who are on antituberculosis therapy then HAART should be modified if necessary. TB treatment should only be modified when a patient has developed intolerance of, or severe toxicity from, HIV drugs or has evidence of genotypic resistance to specific HIV drugs, thus limiting HAART therapy to agents which are likely to interact with antituberculosis therapy.

These factors (intolerance, toxicity and resistance) may sometimes necessitate prolongation of duration of TB treatment.

The gold standard for diagnosis of tuberculosis is microscopy followed by culture and drug sensitivity testing. Molecular diagnostics may be valuable in reducing the time patients spend in isolation facilities when tuberculosis is suspected clinically. Confirmation, by molecular diagnostics, that acid-fast bacilli are not Mycobacterium tuberculosis (MTB) may be useful for clinical management and infection control.

We recommend rapid detection of rifampicin resistance using molecular techniques in patients whose clinical course or initial assessment suggest multidrug resistant tuberculosis. These molecular tests should be used as an adjunct to standard laboratory techniques.

TB treatment

We recommend daily tuberculosis treatment whenever possible. Treatment may be given 5 days a week, but should be intensively supervised. This option may be useful in hospitals or other highly supervised settings. Three times a week directly observed therapy (DOT) should only be given to patients where local logistics enable this to be successfully undertaken.

We do not recommend twice-weekly DOT for treatment of HIV/TB coinfected patients, especially in those with CD4 counts < 100 cells/μL.

Treatment should be started with four drugs (typically rifampicin, isoniazid, pyrazinamide and ethambutol) until sensitivities are known.

We recommend a 6-months treatment regimen for drug sensitive M. tuberculosis outside of the central nervous system (CNS) [at least 182 doses of isoniazid and rifampicin and 56 doses of pyrazinamide and ethambutol]. In drug-sensitive tuberculosis affecting the CNS we recommend 12 months of treatment. This usually consists of 2 months of a four-drug TB regimen, followed by 10 months of isoniazid and rifampicin. Drug-resistant disease should be treated in line with BTS Guidelines: http://www.brit-thoracic.org.uk

Drug interactions and toxicities

Rifampicin is a powerful inducer of cytochrome P450–3A4 and, therefore, careful attention should be paid to potential drug/drug interactions between antituberculosis drugs,
HAART and other concomitant therapy. The alternative use of rifabutin may overcome some of the difficulties in coadministration of rifampicin with protease inhibitors and non-nucleosides.

Overlapping toxicity profiles, e.g. peripheral neuropathy with stavudine and isoniazid, or rash with non-nucleosides and rifampicin can complicate care, as ascribing a cause may be difficult. In some patients, e.g. those with chronic viral hepatitis, there is an increased rate of drug toxicity. In these patients we recommend more frequent monitoring of liver function tests.

Antiretroviral treatment

The following antiretroviral drugs may be used with rifampicin-based regimens of TB therapy. It is important to note that there are few long-term clinical outcome data to support use of these drugs in combination.

(i) Nucleoside/nucleotide reverse transcriptase inhibitors

There are no major interactions with rifampicin or rifabutin.

(ii) Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

Efavirenz may be used at a dose of 800 mg/day in patients weighing >50 kg and the standard dose of 600 mg/day in patients weighing <50 kg. In patients experiencing side effects on these doses, therapeutic drug monitoring may be of value. We recommend that daily rifampicin should not be used with nevirapine.

NNRTI may be used with rifabutin, but the rifabutin dose is increased to 450 mg/day when used with efavirenz. No dose modification is required when rifabutin is used with nevirapine, however, we do not recommend use of this combination.

(iii) Protease inhibitors (PIs)

Rifampicin should not be used with un-boosted PIs. Data on boosted PI regimens, e.g. lopinavir/ritonavir with rifampicin, show an increased risk of hepatotoxicity and the need in some patients (based on therapeutic drug monitoring [TDM]) to increase the dose of lopinavir to four tablets twice daily. There is a lack of good clinical and virological outcomes using these combinations.

Rifabutin can be used with un-boosted PI but dose modifications of PI are needed and the dose of rifabutin halved to 150 mg/day. There are few data to support use of rifabutin with a boosted PI but if it is used the dose of rifabutin needs to be reduced to 150 mg three times a week. The dose of boosted PI remains unaltered. In these situations TDM should be used.

We recommend that TDM of NNRTI and PI should be performed when drug regimens are complex. Drug levels of antituberculosis drugs should be measured when there is clinical concern regarding absorption or response to TB therapy.

Starting HAART

When to start antiretroviral therapy in patients who have tuberculosis is a balance between potential overlapping toxicities, drug interactions and possible immune reconstitution vs. the risk of further immune suppression with its associated increase in morbidity and mortality. We recommend that patients who have a CD4 count consistently > 200 cells/µL while receiving treatment of tuberculosis should wait until their antituberculosis therapy is completed before starting HIV therapy (see BHIVA guidelines for the treatment of HIV-infected adults with antiretroviral therapy in this Supplement).

For patients with CD4 counts between 100 and 200 cells/µL we recommend deferring starting HIV therapy until completion of the intensive phase of antituberculosis treatment (after 2 months).

For patients with CD4 counts < 100 cells/µL there are no data to support either immediate or deferred HAART. In this situation we recommend that patients should be recruited to clinical trials which address this question. If that is not possible, then patients should be started on HAART as soon as is practical after starting antituberculosis therapy.

DOT

This is regarded as a gold standard for treatment of TB but it may not be possible to deliver all elements of the DOT package. Witnessed supervision of treatment may be impracticable in every case and it is important to remember that patient-centred management is the core of successful TB treatment. We recommend that DOT be used in all cases of multidrug-resistant TB.

Tuberculin skin test

Tuberculin skin testing is less useful in patients with HIV infection compared with HIV-uninfected patients. We do not recommend tuberculin skin testing in patients with suspected HIV/TB coinfection or as a screening test for tuberculosis in HIV-infected patients. New immune-based detection tests (such as those using gamma interferon production from TB specific T cells) appear to have better sensitivity than tuberculin tests, however, correlation of positive results with outcome in patients with low CD4 counts is required.
TB chemoprophylaxis

We do not recommend routine chemoprophylaxis for all HIV infectious patients. Close contacts of people who have infectious TB should be followed up and offered chemoprophylaxis (see BTS guidelines). Data suggest that HAART is effective in reducing the incidence of new tuberculosis and we recommend that all HIV-positive patients should be offered HAART (based on needs as outlined in the BHIVA HIV treatment guidelines).

Relapse and treatment failure

Patients with tuberculosis, with or without HIV infection, who appear to fail treatment or who relapse despite therapy pose particular management problems and should be referred to and discussed with clinical colleagues who have expertise in the management of HIV/TB.

Control and prevention of TB

Every hospital/trust should have in place a policy for the control and prevention of TB. Specific consideration should be made to establishing protocols for prevention of transmission of TB to and from immunosuppressed patients.

Table 1 Abbreviations

AIDS, acquired immune deficiency syndrome
ALT, alanine aminotransferase
AST, aspartate aminotransferase
AUC, area under the curve
BHIVA, British HIV Association
BTS, British Thoracic Society
CDC, Centers for Disease Control and prevention
CMV, cytomegalovirus
CNS, central nervous system
CXR, chest X-ray
CYP, cytochrome
d4T, stavudine
ddc, zalcitabine
ddi, didanosine,
DOT, directly observed therapy
E, ethambutol
H, isoniazid
HAART, highly active anti-retroviral therapy
HIV, human immunodeficiency virus
IRIS, immune reconstitution inflammatory syndrome
IUATLD, International Union against Tuberculosis and Lung Disease
MDR-TB, multidrug resistant tuberculosis
NNRT, non-nucleoside reverse transcriptase inhibitor
PAS, para-aminosalicylic acid
PCR, polymerase chain reaction
P-gp, P-glycoprotein
Pl, protease inhibitor
PPD, purified protein derivative
R, rifampicin
TB, tuberculosis
TDM, therapeutic drug monitoring
WHO, World Health Organization
Z, pyrazinamide

1.0 Introduction

Worldwide, HIV infection is the foremost risk factor for development of active TB [1–4].

All patients with TB, regardless of their perceived risk of HIV infection, should be offered an HIV test as part of their TB treatment package. In the UK, clinicians are caring for increasing numbers of HIV-TB coinfected patients. TB is now the second commonest opportunistic infection in the UK. In 2003 TB contributed to 27% of all AIDS diagnoses [5–7].

The clinical and radiographic presentation of such individual’s disease may be atypical. Compared to the immune competent general population, HIV-infected patients with active pulmonary TB are more likely to have normal chest radiographs, or be smear negative/culture positive [8–11].

The clinician caring for HIV-infected patients therefore needs to have a high index of suspicion for TB in symptomatic individuals. As the investigation and treatment of both TB and HIV require specialist knowledge and expertise, it is mandatory to involve specialist HIV, respiratory and infectious diseases physicians in patient care.

These guidelines have been drawn up in response to a perceived need for a clinical knowledge base covering the treatment of both HIV and TB in coinfected patients in the UK. These guidelines do not cover HIV-infected children with TB. Although we support the policy of testing all TB patients for HIV, these guidelines do not provide advice on HIV testing in adults with newly diagnosed TB. These treatment guidelines have been written to help physicians manage HIV-infected patients with confirmed or suspected TB. They are based on evidence where it is available but some recommendations have to rely on expert opinion until data from trials are made available. These guidelines are not a manual for treatment of HIV/TB coinfection and should be regarded as
an adjunct to the BHIVA treatment of HIV guidelines and the BTS guidelines on TB.

These documents can be downloaded from http://www.bhiva.org and http://www.brit-thoracic.org.uk

BHIVA is aware of and involved in the creation of NICE guidelines on TB, which will be available in 2005 but felt that until that time some guidance on TB in HIV should be made widely available.

Recommendations for the treatment of TB in HIV-infected adults are similar to those for HIV-uninfected adults. However, there are important exceptions.

(1) Some intermittent treatment regimens are contraindicated in HIV-infected patients because of unacceptably high rates of relapse, frequently with organisms that have acquired rifamycin resistance. Consequently, patients with CD4 counts < 100/μL should receive daily or a minimum of three times weekly antituberculosis treatment.

(2) Adherence strategies including DOT are especially important for patients with HIV-related TB.

(3) HIV-infected patients are often taking medication, which might interact with antituberculosis medications, e.g. rifampicin, which interacts with antiretroviral agents and other anti-infectives, e.g. fluconazole. Drug absorption may also be affected by the stage of HIV infection.

(4) There are overlapping toxicity profiles and drug/drug interactions with some antituberculosis and antiretroviral drugs that further complicate the concurrent use of HAART and TB treatment.

(5) There are also concerns about the timing of commencement of HAART in relation to the start of TB treatment in the context of preventing the risk of further HIV progression and the occurrence of paradoxical reactions.

2.0 Aims of TB treatment

It should be noted that the treatment of tuberculosis has benefits not only for the individual but also for the community.

The aim of TB therapy is:

(1) to cure the patient of TB; and

(2) to minimize the transmission of MTB to both immune suppressed and immune competent persons.

2.1 Laboratory diagnosis

The quality of any investigation is related to the quality of the specimen and the request. Therefore there must be close liaison with the mycobacterial laboratory.

2.1.1 Microscopic smears

Microscopic smears remain an essential part of TB diagnosis. Results should be available within 1 working day.

2.1.2 Cultures

These are central to the confirmation and identification of the mycobacterium and for drug susceptibility testing. More rapid results are obtained from liquid media, which usually grows MTB in 7–28 days.

Identification of mycobacterium based on morphology, growth and biochemical characteristics are performed at mycobacterium reference centres. Rapid gene probes can be used but this should be fully discussed with the laboratory. These are less sensitive than culture and are used mainly on respiratory specimens. These are often requested when it is important to differentiate the diagnosis of MTB from other mycobacteria for which treatment may be different and there are no infection control concerns. However, it should be noted that all specimens even those that are negative on PCR still require culture and that a negative PCR does not exclude TB and a positive PCR does not indicate the drug susceptibility profile. In many cases the treatment conundrum is whether the patient has *Mycobacterium avium* or MTB and often the physician will wait for the routine identification before altering the standard 4-drug regimen. Some physicians prefer to replace rifabutin for rifampicin in this situation. When opportunistic mycobacteria are identified then the regimen can be modified appropriately.

2.1.3 Drug susceptibility tests

These are usually available within 10–21 days of the laboratory receipt of the isolates and are performed by standard assays. Molecular detection of rifampicin resistance (and pyrazinamide) is available although it is not 100% sensitive. These molecular tests are useful when drug resistance is suspected, as about 95% of patients who are rifampicin resistant will also be isoniazid resistant.

Patients with gene probe positive rifampicin resistance should be treated as multidrug-resistant tuberculosis (MDR-TB), until the full resistance profile from cultures are available.

2.1.4 Rapid detection of active and latent tuberculosis infection in HIV-positive individuals

The lack of sensitivity of the tuberculin test and the poor specificity because of antigenic cross-reactivity with BCG vaccination means that an accurate test for active or latent TB in HIV individuals is needed.

Tests using either whole blood or blood mononuclear cells have been developed which measure interferon
gamma production from TB-specific T cells responding to MTB antigens ESAT-6 or CFP-10 [12].

Using an enzyme linked immunospot (ELISPOT) assay, a study from Zambia and the UK diagnosed active TB in 90% of 39 individuals tested. Unfortunately, although this technology was better at picking up latent TB than PPD testing in HIV-positive persons, it was still not as sensitive when compared to HIV-negative patients. Larger studies are needed and correlations of ELISPOT responses with patient’s CD4 counts need to be made. The reproducibility of the test also needs to be evaluated in HIV-positive patients and long-term outcomes measured.

2.2 Type and duration of TB treatment

2.2.1 Treatment regimens

Because of the relatively high proportion of adult patients in the UK with TB caused by organisms that are resistant to isoniazid, four drugs are necessary in the initial phase for the 6 month regimen to be maximally effective. From Mycobnet data (UK TB resistance database, Health Protection Agency) the overall isoniazid resistance rate in the UK is 6% and higher in non-white ethnic groups and those with prior treatment. The highest rates have been found in London. Thus, in most circumstances, the treatment regimen for all adults with previously untreated TB should consist of two phases.

1) A 2-month initial phase of isoniazid, rifampicin, pyrazinamide and ethambutol. If (or when) drug susceptibility test results are known and the organisms are fully susceptible, ethambutol need not be included. This is followed by a continuation phase of treatment is given for either 4 or 7 months. The 4-month continuation phase should be used in the majority of patients.

TB therapy can be given five times a week with standard doses. Although there are no formal clinical trial data, considerable clinical experience suggests that 5 days-a-week drug administration by DOT is equivalent to 7 days-a-week treatment – and thus either may be considered ‘daily’ [AIII].

2) The 6 months short course drug combination should be recommended to all HIV-positive patients with pulmonary tuberculosis wherever possible [AII]. All patients should be given pyridoxine (vitamin B6) 10–25 mg with isoniazid dosing.

There are important exceptions.

2.2.2 Longer continuation phase [AII]

A 7-months continuation phase is recommended for certain groups, for example

1) patients with drug-susceptible organisms whose initial phase of treatment did not include pyrazinamide;

2) patients with cavitary pulmonary disease who remain sputum culture positive at month 2 of treatment.

A 10-month continuation phase is recommended for patients with CNS involvement, e.g. meningitis, tuberculomata.

2.2.3 Intermittent therapy [AII]

It is recommended that patients should receive daily therapy. However, intermittent treatment is an option [13,14]. The indications for this in HIV-positive individuals are almost the same as for patients without HIV infection. Intermittent therapy can be given three times per week with dose modification. Two dosing strategies should be avoided, as acquired rifamycin resistance has been associated with their use in HIV patients [AII]:

1) once-weekly isoniazid–rifapentine in the continuation phase should not be used in any HIV-infected patient; and

2) twice-weekly isoniazid–rifampicin or -rifabutin should not be used for patients with CD4 counts <100 cells/µL.

In two studies, patients with acquired rifamycin resistance had very low CD4 counts at the time of TB diagnosis (<60 cells/µL) [15–17].

These data have led the CDC in the USA to recommend that persons coinfected with HIV and TB who have CD4 cell counts <100 cells/µL should not be treated with highly intermittent (i.e. once or twice weekly) regimens. Patients already on highly intermittent regimens should switch over to daily or three times a week as soon as practicable.

2.2.4 Use of rifabutin [B11]

Rifabutin has been successfully used instead of rifampicin in treatment of TB in HIV-negative patients [18,19]. In HIV patients receiving complex antiretroviral regimens, where there is a risk of drug/drug interactions with rifampicin, rifabutin may be substituted. Rifabutin showed similar efficacy to rifampicin in a single blind, randomized study of 50 HIV-positive patients in Uganda and in a cohort study of 25 patients in the USA [20,21]. Although rifabutin seems to be equivalent to rifampicin, there are no long-term data on which to make comparisons. Despite the paucity of data regarding use of rifabutin in HIV-positive patients, it is frequently used in the treatment of TB in HIV. This is because rifabutin may be administered with antiretroviral regimens that include PIs. However, non-PI-based regimens are possible, especially in HAART-naive patients.
We recommend that rifampicin should remain the drug of choice whenever possible.

2.2.5 Use of rifapentine [DII]
Rifapentine has a long serum half-life, which theoretically would allow once-weekly directly observed therapy during the continuation phase of TB treatment. In the initial phase of treatment of TB in HIV-negative patients rifapentine has unacceptable 2-year microbiological relapse rates and cannot be recommended. Data on its use in the continuing phase of treatment is encouraging, but this is accrued from studies of HIV-negative patients.

There are few data regarding the interaction of rifapentine with HAART. Development of rifapentine resistance appears more frequent in TB/HIV coinfected patients and more data are needed before rifapentine can be recommended for use in this patient group [22].

2.2.6 Duration and effectiveness of TB treatment
In the absence of data from clinical trials, it is not known if duration of treatment of TB in HIV-infected patients should be for longer than in HIV-uninfected patients. The few data that exist suggest that in HIV-infected patients duration of treatment for tuberculosis sensitive to first line therapy should be no different to HIV-uninfected patients.

A review of six studies of patients with HIV infection and three studies of patients without HIV infection given treatment for 6 months (or longer) demonstrated considerable variability in published study design, eligibility criteria, site of disease, frequency and method of dosing, and outcome definitions. In the reported studies, HIV-infected patients had cure rates of 59–97%, successful treatment rates of 34–100% and relapse rates of 0–10%. In patients without HIV infection, cure rates were 62–88%, successful treatment occurred in 91–99% and relapse rates were 0–3%. Although the relapse rates appeared higher in some studies of coinfected patients other outcomes were comparable when 6 months regimens were used.

We recommend that for drug sensitive TB, not involving the CNS, regimens of 6 months should be given [16,23–27] [AII].

Some or all of these factors have a role in explaining the differences in the present data. A multicentre study from the USA found no difference between TB relapses with regimens of 6 and 9 months duration. However, very few patients relapsed (two and one patients, respectively) [28,29].

The risk of relapse of TB for HIV-infected patients is the same as that for HIV-uninfected patients if rifampicin is used throughout (for at least 6 months). Long-term randomized trials are needed to resolve the question of duration of TB therapy in HIV-infected patients.

In HIV-infected patients HAART may reduce the risk of relapse of TB [30–32]. This statement is supported by data showing a reduction in the incidence of TB with HAART and hence it might be hypothesized that there will be a reduced rate of exogenous reinfection and/or reactivation in patients who have HAART-induced improvements in CD4 count.

2.2.7 Baseline and follow-up evaluations after starting TB treatment [AIII]
Monitoring of therapy is as follows:

1. A baseline absolute CD4 count and percentage should be obtained.
2. Baseline measurements of serum aminotransferases [aspartate aminotransferase (AST) and or alanine aminotransferase (ALT)], bilirubin, alkaline phosphatase, and serum creatinine, and a platelet count should be obtained. Liver function tests should be rechecked at 1–2 weeks if asymptomatic (see British Thoracic Society (BTS) Guidelines).
3. All patients should have serological tests for hepatitis B and C viruses at baseline.
4. Testing of visual acuity with Snellen charts should be performed when ethambutol is used (see BTS guidelines).
5. Patients with pulmonary TB who are not improving on treatment should have a repeat sputum smear and culture if the patient still has a productive cough after completing 2 months of treatment.
6. A chest radiograph should be performed if subsequent progress after 2 months is unsatisfactory. In pulmonary TB, a baseline and ‘completion of treatment’ chest radiograph are necessary.
7. Other evaluation, e.g. additional chest radiographs, ultrasound or CT scans may be indicated, depending on the clinical need.

2.2.8 Definition of completion of TB therapy
Treatment for a defined number of days without accounting for the number of doses taken may result in under treatment. Therefore, determination of whether or not treatment has been completed should be based on the total number of doses taken—not solely on the duration of therapy. For example: (1) a 6-month daily regimen (given 7 days/week) should consist of at least 182 doses of isoniazid and rifampicin, and 56 doses of pyrazinamide; (2) if the drugs are administered by DOT (5 days/week), the minimum number of doses of rifampicin and isoniazid is 130 and 40 doses of pyrazinamide.

It is recommended that all of the doses for the initial phase be taken within 3 months and those for the 4-month continuation phase be taken within a 6-month period. The
2.2.9 Interruptions of therapy [AIII]
These are common in the treatment of HIV-associated tuberculosis. Data to support recommendations are scant. We agree with the CDC that there are few data to guide the management of interruptions. They suggest the following:

1. If the interruption occurs during the initial phase of treatment and the interruption is 14 days or more in duration, treatment should be restarted from the beginning.
2. If the interruption is less than 14 days, the treatment regimen should be continued.

Note, in both cases the total number of doses prescribed for the initial phase should be given.
3. For patients who were smear positive initially, continued treatment to complete the planned total number of doses is needed. Thus,

   (i) If the patient has received less than 80% of the planned total doses and the lapse is 3 months or more in duration, treatment should be restarted from the beginning.
   (ii) If the interruption is less than 3 months in duration, treatment should be continued to complete a full course. Studies have not been performed in HIV-infected patients in order to confirm this observation and physicians should be cautious when treating patients who have had interruptions of therapy.

Regardless of the timing and duration of the interruption, DOT should be used.
If the patient was already being managed with DOT, additional measures may be necessary to ensure completion of therapy, e.g. transport, food, social services [33].

3.0 Drug/drug interactions
Drug/drug interactions between HIV and TB therapy arise through shared routes of metabolism and are often due to enzyme induction or inhibition [34,35].

One important family of enzymes is the hepatic cytochrome P450 (CYP) system. The isofrom CYP3A4 is involved in the metabolism of many drugs including the protease inhibitors and NNRTIs, which makes up the core of most HAART regimens.

The NNRTIs and PIs have clinically important drug interactions with the rifamycins, as the latter are potent inducers of CYP3A4 [36,37].

However, the inducing effect of rifampicin not only takes at least 2 weeks to become maximal but will also persist for at least 2 weeks after rifampicin has been stopped. If antiretrovirals have been started or changed at the end of TB treatment, this persistent effect on enzyme induction should be taken into consideration. In addition, rifampicin increases the activity of the efflux multidrug transporter P-glycoprotein (P-gp) that contributes to the elimination of PI [38,39].

Rifabutin is a less potent inducer of CYP3A4. Unlike rifampicin, it is also a substrate of the enzyme [40]. Therefore any CYP3A4 inhibitors will increase the concentration of rifabutin but will have no effect on rifampicin metabolism. Thus, when rifabutin is given with PI, which are inhibitors of CYP3A4, its plasma concentration and that of its metabolites may increase and cause toxicity.

Individual drug/drug interactions between rifamycins and antiretroviral agents are shown in Tables 1 and 2. The complexity of drug/drug interactions requires expertise in use of both antiretroviral and anti-TB drugs. One particular drug interaction should be noted: the metabolism of corticosteroids is accelerated by rifampicin and therefore doses of such drugs, e.g. prednisolone, which are commonly used in TB should be increased proportionately.

3.1 Rifamycins and nucleoside/nucleotide analogues
Most nucleosides have either unknown or little change in pharmacokinetics when given together with rifampicin-based regimens. Rifampicin reduces the area under the curve (AUC) (concentrations curve or total drug exposure) and increases the clearance of zidovudine via the mechanism of increased glucuronidation of zidovudine. This is not clinically significant and dose alteration is not required. In contrast, rifabutin does not appear to affect the clearance of zidovudine [41,42].

The previous formulation of didanosine contained a buffer, which affected the solubility and absorption of rifampicin and ingestion of the drugs had to be separated.
in time. This is no longer necessary as buffer-free enterico-
coated didanosine is routinely used.

3.2 Rifamycins and PIs

3.2.1 Rifampicin

Rifampicin causes a 75–95% reduction in serum concen-
trations of PI other than ritonavir. Such reductions lead to
loss of antiretroviral activity of PI-containing regimens
and consequently can result in the emergence of resistance
to one or more of the other drugs in the HAART regimen.

Currently, most patients are given combinations of PI,
which includes low-dose ritonavir (usually 100 mg per
dose) in order to take advantage of its enzyme inhibiting
properties. In effect, ritonavir boosts the concentrations of
the other PI allowing easier and more tolerable dosing.

Data from the drug/drug interaction of rifampicin with
lopinavir/ritonavir suggest that ritonavir at this low dose
may compensate for the induction effect of rifampicin on
lopinavir metabolism [43,44].

Preliminary data suggested that ritonavir 100 mg twice
daily may be used with daily rifampicin. Once daily
saquinavir/ritonavir has also been used [45]. However,
recent studies of subjects exposed to rifampicin twice daily
together with ritonavir-boosted saquinavir suggest that rifampicin at this low dose
can result in the emergence of resistance to one or more of the rifamycins.

3.2.2 Rifabutin

Rifabutin can be used with single (unboosted) PI except
saquinavir. However, because of the balance between
rifabutin induction and protease inhibition of CYP3A4,
when this combination is used a modification in the dose of
the PI may be required (see Table 2) and the dose of
rifabutin should be decreased by half to 150 mg. If PI are
used with 100 mg ritonavir boosting, then the dose of
rifabutin should be reduced to 150 mg and should only be
given three times a week.

Complex interactions may occur when a rifamycin is
given with salvage regimens such as two PI plus boosted
ritonavir, or with a boosted or non-boosted PI and a NNRTI.
These combinations are used in patients who have had
virological failure or intolerance to simpler regimens.

These multiple interactions have yet to be fully studied and
there are no clear guidelines regarding dosing of rifabutin
when given in this situation. Here TDM should be used.

3.3 Rifamycins and NNRTIs

The NNRTI nevirapine is both partially metabolized by CYP
3A4 and also induces this enzyme system. The other
commonly used NNRTI efavirenz behaves in a similar way.
Because of this inducing effect the clinical use of these
drugs together with the rifamycins is complex.

3.3.1 Rifampicin

When rifampicin is used with efavirenz-based regimens for
patients >50 kg an increase in the dose of efavirenz to
800 mg/day is required. Standard doses of efavirenz are
used if the patient weights <50 kg [47–49] [AII].

Rifampicin reduces the AUC and Cmax of nevirapine in
HIV-infected patients by 31% and 36%, respectively.
Although no major impact on clinical and virological
responses have been reported data suggest that rifampicin
(two times a week) may be given with nevirapine-based
regimens [50–53].

These observations have led some guideline committees
to suggest that nevirapine may be co-administered with
rifampicin in standard doses during the treatment of
coinfection. However, the numbers of patients studied are
small and follow up is limited.

We recommend that daily rifampicin should not be used
with nevirapine [AIII].

3.3.2 Rifabutin

If rifabutin is used with efavirenz, the rifabutin dose should
be increased to 450 mg/day because of the induction effect of
efavirenz. Rifabutin and nevirapine have been given
without any adjustment in either of their dosages.
More data are needed before this strategy can be
recommended.

3.4 Isoniazid

Pharmacokinetic or clinical interactions between isoniazid
and antiretroviral agents have not been extensively
studied. In vitro studies have shown that isoniazid, at
clinically relevant concentrations, is a reversible inhibitor
of CYP3A4 and CYP2C19, and that it mechanistically
inactivates CYP1A2, CYP2A6, CYP2C19 and CYP3A4 in
human liver microsomes. Isoniazid, co-administered with
drugs such as PI and NNRTI, which are metabolized by
these isoforms, may result in significant drug/drug
interactions.

These interactions might be significant when isoniazid is
given alone to treat latent TB infection in an HIV
coinfected patient who is receiving PI or NNRTI. The pharmacokinetic and clinical consequences of concurrent therapy with rifampicin (inducer) and isoniazid (inhibitor) together with PI and NNRTI on CYP3A4 have not been studied but may be clinically important [54,55]. The use of drug therapeutic monitoring may be useful in such situations.

3.5 Non-rifamycin regimens

HIV-related TB may be treated with non-rifamycin-containing regimens. These should be only contemplated in patients with serious toxicity to rifamycins, where desensitization/reintroduction has failed, or in those with rifamycin-resistant isolates.

Drug/drug interactions might be fewer but a non-rifamycin regimen is inferior to a rifampicin-based regimen for the treatment of HIV-related TB.

It should be noted that high TB relapse rates, greater than 15%, have been seen when an initial 2 months rifampicin-containing regimen is then switched in the continuation phase to isoniazid and ethambutol.

4.0 Overlapping toxicity profiles of antiretroviral drugs with antituberculosis therapy

Adverse reactions to drugs are common among patients with HIV-related TB, especially if taking HAART concomitantly.

Rash, fever and hepatitis are common side-effects of antituberculosis drugs, especially rifampicin, isoniazid and pyrazinamide. The NNRTI and cotrimoxazole may also cause similar features. The co-administration of these drugs can lead to difficult clinical management decisions if these side effects occur, especially when HAART and TB drugs are started concurrently.

A total of 167 adverse events were recorded in 99 (54%) of the 183 patients for whom data on therapy were available in a study from the south-east of England [56].

Adverse events led to cessation or interruption of either their TB or HIV therapy in 63 (34%) of the 183 patients. The most common side effects usually occurred in the first 2 months of treatment and were peripheral neuropathy in 38 patients (21%), rash in 31 patients (17%), gastrointestinal intolerance in 18 patients (10%) hepatitis in 11 patients (6%) and neurological events in 12 patients (7%).

The majority of adverse reactions occurred within the first 2 months of starting concurrent therapies. Rifampicin was frequently implicated by the treating physicians, and was responsible for almost two-thirds of adverse events.

4.1 Hepatotoxicity

Hepatotoxicity is a common and potentially serious adverse event. It is defined as:

1. a serum AST or ALT level of more than three times the upper limit of normal in the presence of symptoms, or
2. a serum AST or ALT greater than five times the upper limit of normal in the absence of symptoms.

Hepatotoxicity due to isoniazid in the general population increases with age, occurring in less than 0.3% of those under 35 years vs. about 2.3% in those older than 50 years. It is also more likely in those with a heavy alcohol intake, with hepatitis C coinfection and in those who are receiving therapy with rifampicin. High rates of adverse reaction requiring changes in therapy have been reported in HIV-infected patients who are likely to have some or all of the other risk factors noted above. The rates of adverse reaction were 26% in one HIV cohort compared with 3% in the HIV uninfected group. Other studies have shown similar results [57,58].

If hepatitis develops, then all potentially hepatotoxic drugs including isoniazid, rifampicin, pyrazinamide and others, e.g. antivirals and cotrimoxazole, should be stopped immediately.

Serological testing for hepatitis viruses A, B, and C, if not already done, should be performed and the patient asked about any exposure to other possible hepatotoxins, especially alcohol.

As resolution of the hepatitis may be prolonged and until the cause of the hepatitis is identified then, if necessary, it would be reasonable to treat with two or more antituberculosis medications without significant risk of hepatotoxicity, such as ethambutol, streptomycin, amikacin/kanamycin, capreomycin, or a fluoroquinolone.

Monitoring of serum AST (or ALT) and bilirubin and any symptoms should be performed frequently and once the AST level drops to less than two times the upper limit of normal and symptoms have significantly improved, then first line medications can be restarted using a reintroduction regimen (Table 5).

If the drugs cannot be restarted or the initial reaction was life threatening then an alternative regimen can be used (see below).

4.2 Pre-existing liver disease

The risk of hepatotoxicity in these patients is greatest with pyrazinamide then rifampicin and then isoniazid. Isoniazid and rifampicin are essential drugs in short course TB treatment regimens and should be used whenever possible even in the presence of pre-existing liver disease.

(Continued)
However, if the serum AST is more than three times normal due to chronic liver disease even before starting treatment, then other regimens can be used. For example,

1. Avoid pyrazinamide and treat with isoniazid and rifampicin for 9 months, adding ethambutol until isoniazid and rifampicin susceptibility are demonstrated [AIII].

2. Avoid isoniazid and treat with rifampicin, ethambutol, and pyrazinamide for 2 months, followed by 10 months of rifampicin and ethambutol [BIII].

3. Use only one potentially hepatotoxic agent in patients with severe liver disease and treat with rifampicin plus ethambutol for 12–18 months preferably with another agent (such as a fluoroquinolone), for the first 2 months; however, there are no data to support this recommendation [CIII].

In all patients with pre-existing liver disease, frequent clinical and laboratory monitoring should be performed to detect drug-induced hepatic injury.

Monitoring should be performed more frequently (at least 2 weekly initially) in those with underlying liver disease. This should include biochemical and haematological assessments and the prothrombin time. Patients should be told to report to their physician if they develop symptoms such as anorexia, nausea, vomiting, abdominal pain or jaundice [59,60].

4.3 Gastrointestinal side effects

These are common especially in the first 2–3 weeks after starting antituberculosis therapy. If patients develop epigastric pain, vomiting or nausea with first line drugs, have no evidence of hepatic disease and are unresponsive to symptomatic treatment, e.g. with antiemetics, then they can:

1. take their treatment with meals unless on less than 600 mg rifampicin daily; food delays or decreases the absorption of antituberculosis drugs but these effects are moderate and of little clinical significance; or

2. change the time of dosing.

Patients should avoid dividing doses or changing to alternative drugs if at all possible; however, sometimes dividing the dose of, e.g. pyrazinamide, can improve tolerability.

4.4 Peripheral neuropathy

The nucleoside analogues didanosine, zalcitabine and stavudine may all cause peripheral neuropathy and an additive toxicity of isoniazid when used with d4T has been demonstrated. These antiretroviral drugs can be avoided in...
the HAART-naive population and alternatives should be found if possible in those already on these drugs [AII].

Pyridoxine 10–25 mg daily should be used in all HIV-positive patients receiving isoniazid [56,61].

5.0 Drug absorption

5.1 Malabsorption of drugs

Malabsorption of antimycobacterial drugs with all first line therapies as well as ethionamide and cycloserine has been reported in coinfected persons.

Absorption of drugs may be less in those patients with a low CD4 count, whether it be due to HIV enteropathy or other specific HIV-related gut diseases resulting in sub therapeutic serum and drug levels and consequently associated with treatment failure and drug resistance. Although some studies show lower peak concentrations of rifampicin and ethambutol as well as lower AUC compared with controls, there are other data suggesting that rifampicin is well absorbed in HIV patients, even those with AIDS or with diarrhoea [62–68].

5.2 Therapeutic drug monitoring (TDM)

5.2.1 TDM of TB drugs [BII]

Based on the limited amount of available data TB drug therapeutic monitoring might be useful (but is often not very helpful) in:

- patients who are at high risk of malabsorption of their TB drugs,
- patients who are responding inadequately to directly observed therapy with first line drugs,
- patients being treated for MTB,
- patients who are on non-standard TB regimens or taking non-standard doses.

One of the problems with monitoring antimycobacterial drugs in HIV-positive patients is that the kinetics of absorption are not predictable. It is, therefore, difficult to know when to measure a peak serum level; and it is probably best to assess this in the individual patient by checking levels at more than one time point post dose, e.g. 1, 2 and 4 h. Decisions over dosing may be difficult as there can be long delays in results returning to the physician [62–68].

5.2.2 TDM of HIV drugs [BII]

TDM may be relevant for PI and NNRTI especially when regimens are complex, when no formal PK data are available to guide the physician and when virological failure occurs.

6.0 When to start HAART

The optimal time to start HAART in TB/HIV patients is not known. Physicians have to balance the risk of HIV progression if HAART is delayed against the risk of having to discontinue therapies because of toxicities, side effects, paradoxical reactions or unforeseen drug/drug interactions if HAART is started. Similar routes of metabolism and elimination and extensive drug interactions may result in subtherapeutic plasma levels of antiretroviral agents and furthermore, overlapping toxicity profiles may result in the interruption or alteration of TB and HIV regimens with potential subsequent microbiological or virological failure. In coinfected patients delaying the start of HAART can simplify patient management, limit the development of side-effects and drug interactions and the risk of immune restoration reactions.

Deaths in the first month of TB treatment may be due to TB, while late deaths in coinfected persons are attributable to HIV disease progression [69–71].

Patients with HIV disease and a CD4 cell count >200 cells/μL have a low risk of HIV disease progression or death during the subsequent 6 months of TB treatment. They should have their CD4 cell count monitored regularly and antiretroviral therapy withheld if possible during the short course tuberculosis treatment.

Most patients with TB in the UK present with a low CD4 count, often <100 cells/μL. Some recommend that anti-

Add in ethambutol once all the other drugs are at full dose. If the reaction is severe start with one-tenth of the first day dose for each drug. Commonly used modifications include those with 3 days between each drug being restarted after the full introduction of the previous drug.
retroviral therapy be delayed until the first 2 months of TB therapy has been completed. Others would only recommend this strategy for those with CD4 counts > 100 cells/µL, because of the short-term risk of developing further AIDS defining events and death [72–76].

One retrospective study has shown that starting HAART early in severely immunosuppressed HIV-positive patients presenting with TB is associated with decreased mortality and a lowering of the rates of progression [56]. Prospective data on these patients are needed.

6.1 Suggested timing of HAART in HIV/TB coinfection [AII]

1. CD4 count cells/µL < 100—start as soon as possible, dependent on physician assessment (some physicians delay up to 2 months).
2. CD4 count cells/µL = 100–200—start after 2 months of TB treatment
3. CD4 count cells/µL > 200—start after completing 6 months TB treatment

Note that regular 6–8 weekly CD4 count monitoring should be performed. If the CD4 count falls patient may need to start HAART (as per BHIVA treatment guidelines).

7.0 DOT

The use of directly observed therapy is held up as the gold standard by WHO and CDC for the treatment of HIV-related TB especially when using intermittent dosing. It is recommended that all patients with MDR-TB have DOT [AII].

It should be noted that the superiority of DOT over self-administered therapy for the treatment of TB in developing countries is yet to be proven. Controlled, randomized trials performed in South Africa and Pakistan showed similar treatment completion and cure rates for DOT and self-administered TB treatment [77–79].

In contrast, investigators in Thailand found higher treatment completion and cure rates in patients assigned to DOT compared to self-administered treatment; however, special conditions pertained to the patients in this study [80].

Patient-centred care should be at the core of multi-disciplinary management and should therefore include an adherence strategy that emphasizes DOT. This may include DOT/supervised therapy for antivirals [81] [BIII].

However, there are no published data on the utility and efficacy of combined HAART/TB DOT in treating coinfection.

DOT usually requires that patients be observed to ingest each dose of antituberculosis medication, to try and ensure the completion of therapy. Any treatment plan should be individualized to incorporate measures that facilitate adherence to the drug regimen. Such measures may include, for example, social service support, treatment incentives, housing assistance, referral for treatment of substance misuse, and co-ordination of TB services with those of other providers.

8.0 Tuberculin skin testing

In the pre-HIV era about 75–85% patients with newly diagnosed pulmonary tuberculosis had a positive response to 5 units (intermediate strength) PPD testing.

In HIV and TB coinfection there is a reduction in the proportion of those reacting to PPD as the CD4 count falls, from 50–90% in those who have a CD4 count of = 500 cells/µL down to 0–20% in those patients who have AIDS or advanced HIV infection and a CD4 count equal to 200 cells/µL. This limits the usefulness of the tuberculin test as a diagnostic tool.

Specific nonreactivity to PPD is difficult to distinguish from the general poor immune responsiveness seen in HIV-infected patients, andergy testing using a panel of antigens gives inconsistent and ambiguous results and is not a recommended strategy.

HAART may improve immunological responses to TB but patients most likely to revert from a negative to a positive PPD are those with a rise in CD4 count of > 200 cells/µL from baseline [82–90].

8.1 Who should have tuberculin testing?

A tuberculin test is performed in order to identify those patients who may have latent TB infection so treatment may be given in order to prevent reactivation. The US guidelines recommend that all newly diagnosed HIV patients should have a tuberculin skin test and those with a positive test (>5 mm induration) should be given isoniazid or other chemo-preventative therapy. Whether this policy has any long-term public health impact on TB control in countries where TB has a relatively low prevalence, is not known [91–98].

There are many factors that may affect the usefulness of such a broad strategy. These include the lower PPD-positive rates in HIV-positive patients, the effect of BCG immunization on PPD reactivity, the relative short-term impact of chemo-preventative therapy where there are high rates of exogenous infection and the effect of HAART in preventing tuberculosis reactivation and progression to infection. In newly diagnosed patients with CD4 counts < 400 cells/µL
9.0 TB chemoprophylaxis–HAART or antituberculosis drugs?

Widespread use of HAART has reduced the risk of developing clinical TB among persons infected with HIV and may help bring about further declines when integrated into TB programmes. The effect of HAART on the risk of TB among persons infected with HIV has been examined in several studies. The risk of TB was up to 80% lower among persons prescribed HAART and 40% lower among persons prescribed other non-HAART antiretroviral therapy, than the risk in persons not prescribed antiretroviral therapy. The protective effect of HAART was greatest in symptomatic patients and those with advanced immune suppression but was not apparent in those with CD4 counts > 350 cells/μL [30–32]. Its effect is almost certainly related to improvements in systemic immunity (measured by an increase in the CD4 count) to a point where the risk of new or re-infection is greatly diminished.

There have been several short-term controlled trials in HIV-positive persons showing the protective effect of chemoprophylaxis therapy [99–110]. A protective effect of isoniazid is found only in those who are tuberculin skin test positive. This protective effect appears to last only 2–4 years as compared with 19 years or more in non-HIV populations. Such a short-term effect in HIV-positive patients studied especially in areas of high TB prevalence may be explained by the fact that the majority of the tuberculosis in HIV population arises from exogenous sources and thus are not from reactivation of latent TB but are new. Beyond recognized outbreaks, there is little evidence to suggest that re-infection (as opposed to reactivation) is a major factor in the UK.

A pragmatic but still theoretical approach in those HIV patients who are at increased risk of TB, e.g. immigrants, is to give isoniazid prophylaxis until the CD4 count has risen to above a reasonable threshold, say 200–300 CD4 cells/μL on HAART and then it could be stopped. Data are needed on what the threshold might be as patients may need to be on isoniazid for more than 1 year and the effects of this are relatively unknown.

The routine use of such chemo-preventative therapy in this setting is not recommended [DII].

9.1 The treatment of latent tuberculosis infection

The treatment of latent tuberculosis infection includes:

1. isoniazid for a total of 6–9 months,
2. rifampicin with isoniazid for a total of 3 months,
3. rifampicin alone for 4 months.

Short courses of chemo-preventative therapy using other drugs have been recommended to help overcome poor adherence. Unfortunately rifampicin and pyrazinamide given three times a week for 2 months has been associated with severe and fatal hepatic reactions in five non-HIV patients with a total of 21 cases of liver injury reported to CDC [111].

However, this complication was not seen in the studies of HIV-positive patients taking this regimen.

It is known from RFLP studies that many tuberculosis infections in HIV-positive patients in TB endemic areas appear to be new infections rather than reactivation of the original TB [112]. Isoniazid may prevent such exogenous infection but would then have to be given long term or at least until there was a substantial CD4 rise on HAART [113–115]. There are no current data to support such a strategy.

10.0 Management of relapse, treatment failure and drug resistance

10.1 Relapse

TB relapse is defined as a patient who has become (and remained) culture negative while receiving therapy but after completion of therapy becomes:

1. culture positive again, or
2. has clinical or radiographic deterioration that is consistent with active TB.

Every effort should be made to establish a diagnosis and to obtain microbiological confirmation of the relapse to enable testing for drug resistance.

Most relapses occur within the first 6–12 months after completion of therapy.

Patients whose initial tuberculosis was drug susceptible and who were treated with rifamycin containing regimens using DOT, relapse with susceptible organisms in nearly all cases. In patients who received self-administered therapy or a non-rifamycin regimen and who relapse, the risk of acquired drug resistance is substantial.

The selection of any empirical TB treatment for patients with relapse should be based on the prior treatment regimen and severity of disease.

1. For patients with tuberculosis caused by drug susceptible organisms and who received DOT, initiation of the
standard four-drug regimen is appropriate until the results of drug susceptibility tests are available [AII].

(2) For patients who have life-threatening forms of tuberculosis, at least three additional agents to which the organisms are likely to be susceptible should be included even if the criteria in (1) are fulfilled [AIII].

(3) For patients with relapse who did not receive DOT, and/or who were not treated with a rifamycin-based regimen, or who are known or presumed to have had irregular treatment, or poor adherence then it should be assumed that drug resistance is present and to treat with isoniazid, rifampicin, and pyrazinamide plus an additional two or three agents. Such agents would include a fluoroquinolone, an injectable agent such as streptomycin or amikacin, with or without additional oral drugs such as para-aminosalicylic acid (PAS), cycloserine, prothionamide and clarithromycin [AIII].

10.2 Treatment failure

Treatment failure is the presence of continued or recurrently positive cultures during the course of antituberculosis therapy. After 3 months of multidrug therapy for pulmonary tuberculosis caused by drug susceptible organisms, 90–95% of patients will have negative cultures and show clinical improvement. All patients with positive cultures after 3 months of appropriate treatment must be evaluated carefully to identify the cause of the delayed conversion. Patients whose sputum cultures remain positive after 4 months of treatment should be classified treatment failures.

There are many reasons for treatment failure in patients receiving appropriate regimens. These include:

(1) non-adherence
(2) drug resistance
(3) malabsorption of drugs
(4) laboratory error and
(5) a few patients take a long time to respond as part of extreme biological variation.

If treatment failure occurs, the case should be referred to a regional centre [116]. *Mycobacterium tuberculosis* isolates should be sent to a reference laboratory for drug susceptibility testing to both first and second line agents.

One of the fundamental principles in managing patients with treatment failure is never to add a single drug to a failing regimen, as this leads to acquired resistance to the new drug. Instead, at least two, and preferably three, new drugs to which the patient has not been exposed and susceptibility thought likely should be added.

Empirical regimens usually include a fluoroquinolone and an injectable agent such as streptomycin and an oral agent such as para-aminosalicylic acid (PAS), cycloserine, prothionamide or clarithromycin. Once drug susceptibility test results are available, the regimen should be adjusted according to the results.

10.3 MDR-TB

TB resistant to at least isoniazid and rifampicin (multidrug resistant, MDR) are at high risk of further acquired drug resistance. All such patients, whatever their HIV status, should be referred to regional treatment centres.

Although patients with strains resistant to rifampicin alone have a better prognosis than patients with MDR strains, they are also at increased risk for treatment failure and additional resistance and should be managed in consultation with an expert.

There are no definitive randomized or controlled studies to establish the best regimens for treating patients with various patterns of drug-resistant TB. Such treatment recommendations are based on expert opinion. Surgical resection in the management of patients with pulmonary MDR tuberculosis has had mixed results and its role has not been established in randomized studies.

11.0 Pregnancy and breastfeeding

Because of the risk of TB to the fetus, treatment of TB in pregnant women should be initiated whenever the probability of maternal disease is moderate to high. The initial treatment regimen should consist of isoniazid, rifampicin, and ethambutol. Pyrazinamide can probably be used safely during pregnancy and is recommended by the WHO and the International Union against Tuberculosis and Lung Disease (IUATLD). Although all of these drugs cross the placenta, they do not appear to have teratogenic effects. Streptomycin has harmful effects on the human fetus (congenital deafness) and should not be used and prothionamide is teratogenic.

Note, if pyrazinamide is not included in the initial treatment regimen, the minimum duration of therapy is 9 months.

As in the general population pyridoxine supplementation (10–25 mg/day) is recommended for all HIV-positive patients taking isoniazid, including pregnant women.

12.0 IRIS/paradoxical reactions

Some patients after starting antituberculosis treatment will develop an exacerbation of symptoms, signs, or radiological manifestations of TB. This has been well described in patients without HIV infection, but appears to occur more commonly in HIV-positive patients [117–136].
The aetiology of these reactions is unknown, but it is presumed in HIV disease that they occur at least in part as a consequence of HAART-related reconstitution of immunity leading to an abnormal immune response to tubercle antigens released by dead or dying bacilli [137–142].

These reactions do not have a widely accepted definition. They are characterized by worsening or appearance of new signs, symptoms, or radiographic manifestations of tuberculosis that occur after initiation of HAART and are not the direct result of TB treatment failure or another disease process.

They are often defined as transient but can last many months. They are usually seen when the TB is microbiologically controlled but cases can occur with viable organisms isolated on culture. Such paradoxical reactions have been reported in immunocompetent patients before HIV became prevalent. Worsening of nodal disease occurred in around 10% of some populations and CNS disease with enlarging tuberculomata was sometimes seen.

12.1 Epidemiology
In the HAART era, Immune Reconstitution Inflammatory Syndrome (IRIS) has been reported widely (see Table 6) and occurred in 36% (12 of 33) and 32% (six of 19) of patients in two of these studies but in another paradoxical worsening was not significantly more common in patients receiving HAART (three of 28 cases or 11%) compared with three of 44 cases (7%) in patients not receiving antiretroviral treatment.

Reactions occur within a median of 15 days after HAART. IRIS does not appear to be associated with any particular antiretroviral regimen or drug class. Most patients with IRIS have advanced HIV infection (in one study the median baseline CD4 cell count was 35 cells/μL, and median HIV RNA load was approximately 580,000 copies/mL). Its relationship to the initiation of antiretroviral therapy suggests that, as the immune system recovers from profound immunosuppression, abnormal responses toward mycobacterial antigens occur.

IRIS most often presents with fever and increased or new lymphadenopathy. The skin over the nodes is often inflamed and the nodes can spontaneously rupture. Pleural and pericardial effusions, ascites, psoas abscess, cutaneous lesions and new or expanding CNS tuberculomata have also been described as having worsening pulmonary lesions.

With such small data sets in the literature it is difficult to know who is at risk of IRIS but a low baseline CD4 cell count and a rapid recovery in CD4 numbers appear to be relevant. Cases with dissemination outside the lung may also be at increased risk. HAART started within the first 2 months of tuberculosis treatment was associated with an increased risk of IRIS. This may be due to the high burden of bacilli inducing immunologic changes associated with the rapid rise in CD4 cells.

12.1.1 Diagnosis and management of IRIS [AIII]
The diagnosis of IRIS must be one of exclusion as it can be confused with recrudescence of TB due to treatment failure and with drug hypersensitivity. Other infections common among immunocompromised patients should be excluded. The management of patients with IRIS may require moderate to high-dose corticosteroids to control symptoms. Prednisone or methylprednisolone have been used at a dose of 1–1.5 mg/kg and gradually reduced after 1–2 weeks. It is not unusual for patients to be on these for prolonged periods of time and the dose to be increased again when IRIS relapses or recurs. Physicians should be aware of the metabolic side effects and potential to develop serious infections, e.g. cytomegalovirus (CMV) retinitis in patients receiving high-dose corticosteroids.

Non-steroidal anti-inflammatory agents tend not to be helpful. Temporary discontinuation of antiretroviral therapy has also been advocated but can cause precipitous falls in CD4 counts. Recurrent needle aspiration of nodes or abscesses especially if they become tense and/or inflamed can prevent spontaneous rupture which, if it occurs, can lead to long-term sinus formation and scarring. The use of steroids in this context may lead to necrosis and persistent discharge.

After 2 or more weeks of rifampicin therapy this drug has an inducing effect on the metabolism of corticosteroids such that the corticosteroid is effectively reduced in efficacy by 33–50%.

13 Prevention and control of transmission of HIV-related TB
The guidelines for these are in the Interdepartmental Working Group on Tuberculosis published in 1998 by the
Department of Health [116], and are available on the
Department of Health and Health Protection Agency
websites:
http://www.dh.gov.uk/PublicationsAndStatistics/fs/en

In summary, for good control of TB the following should
be focused on:

1. a recognition that TB is a potential diagnosis;
2. the diagnosis should be confirmed as soon as possible;
3. drug resistance should be considered early in non-
   responding patients or when patients have a history
   compatible with drug resistance;
4. there should be no delay in starting treatment;
5. treatment should be started with appropriate drugs;
6. patients should have supervised therapy.

There should be appropriate accommodation for isola-
 tion of patients with potential TB and those with known TB.
A risk assessment should always be made. There should be
adequate isolation rooms and negative pressure facilities
should be properly monitored. Aerosol generating proce-
dures should not take place except in negative pressure
rooms in patients with suspected or confirmed TB. All
patients with suspected or confirmed pulmonary TB should
be considered potentially infectious until proven otherwise.
There should be no intermingling of HIV-infected or other
immunosuppressed patients with patients who have
potentially or infectious TB [116].

All hospitals should have a TB control plan based on risk
assessment. There should be adequate protection of health
care workers and other contacts.

13.1 Notification

TB is a notifiable disease in the UK as it is in many other
countries.

Concerns over deductive disclosure of HIV status if the
HIV-treating physician notifies a patient can be overcome
as any physician involved in the patients care can notify
the patient.

Contact tracing should follow the BTS guidelines but
requires considerable sensitivity.

14.0 Death and clinico-pathological audit of HIV-associated tuberculosis

Despite diagnosis and treatment, patients with HIV and TB
still die [143]. It is important that as many such patients as
feasible are examined by autopsy after death. This
categorizes the causes of death and enables audit of
medical practice. The significant categories of pathology
include:

1. death from active, progressive TB;
2. death from IRIS affecting one or more critical organs
   (e.g. lung, brain), or from anti-TB drug toxicity;
3. death from other HIV-related or non-HIV-related
diseases in a person who was effectively treated for TB;
4. death from other diseases in a person diagnosed with
   and treated for TB, without laboratory confirmation,
   who shows at autopsy no evidence of having had TB.

If the interval between TB culture positivity and death is
less than or equal to 3 months, culture of tuberculous
autopsy tissue should be performed to evaluate drug
sensitivity and bacterial viability.

Autopsies are either requested by clinicians or (in the
UK) commanded by a Coroner or Procurator Fiscal. If the
autopsy is coronial, every endeavour should be made to
obtain the autopsy report for clinical audit. Before any
autopsy, contact with the appointed pathologist to discuss
the clinico-pathological issues is recommended. Pathology
staff should adopt suitable universal infection control
precautions against airborne and blood borne pathogens.
